Abstract

The answer to the question posed in the title is ‘no’ even though research in macroeconomics and corporate finance reports substantial collateral channel effects on firm investment that amplified the business cycles of the United States and Japan. Working with unique data on land values in 35 major Chinese markets and a panel of firms outside the real estate industry, we estimate standard investment equations that yield no evidence of a collateral channel effect. One reason appears to be that some of the most dominant firms in China are state-owned enterprises (SOEs) which are unconstrained in the sense that they do not need to rely on rising underlying property collateral values to obtain all the financing necessary to carry out their desired investment programs. However, we also find no collateral channel effect for non-SOEs when we perform our analysis on disaggregated sets of firms. We suspect that norms and regulation in the Chinese capital markets and banking sector prevent a collateral channel effect from operating among these firms. We caution that our results do not mean that there will be no negative fallout from a real estate bust on the Chinese economy. There are good reasons to believe there would be, just not through a collateral channel effect.

Gyourko thanks the Research Sponsors Program of the Zell/Lurie Real Estate Center and the Global Research Initiatives Project at Wharton for financial support. Deng and Wu thank the Institute of Real Estate Studies at National University of Singapore for financial support. Wu also thanks the National Natural Science Foundation of China for financial support (No. 71003060). We gratefully acknowledge Jia He and Chaoqun Ren for excellent research assistance.

I. Introduction

In a world without complete contracting, economists long have known that pledging collateral such as owned real estate can allow firms to borrow more, and thus, to invest more (Barro, 1976; Stiglitz and Weiss, 1981; Hart and Moore, 1994). Macroeconomists quickly recognized the implication this insight had for amplifying the business cycle via a so-called “collateral channel” effect (Bernanke and Gertler, 1989; Kiyotaki and Moore, 1997). Essentially, falling asset values reduce the debt capacity of credit constrained firms, which depresses their investment on the downside of the cycle. An analogous positive impact occurs on the upside of the cycle when collateral values are increasing for these firms. Bernanke (1983) concludes that this effect helps account for the extraordinarily large variation in output during America’s Great Depression. Gan (2007a, b) argues that Japan’s cycle also was amplified by a collateral channel effect due to its great property market boom and bust a couple of decades ago.

More recent research finds important collateral channel effects among U.S. firms. Using data from 1993-2007 on a large panel of firms, Chaney, et. al. (2011) report that a \$1 increase in real estate collateral value raises investment by 6 cents. This is large economically, as it implies that a one standard deviation increase in underlying collateral value is associated with over one-quarter of a standard deviation increase in corporate investment. Cvijanovic (2011), who also works with recent U.S. firm data, reports large collateral channel effects. Increases in collateral value are associated with materially higher firm leverage, lower debt costs, and greater investment and equity payouts.

Given China’s growing importance in the world economy and the fact that it has experienced a huge property market boom in recent years, this body of work naturally raises the question of whether there are similar impacts in that country. Data limitations are a key reason

this issue has not yet been addressed. It requires high quality information on both firms and property market values. One of the contributions of this paper is to amass two unique data sets with which to analyze the issue.

The first is a panel of 453 firms from outside the real estate industry that were continuously listed on the Shanghai and Shenzhen exchanges between 2003-2010 (and soon to be 2011). Standard accounting variables typically used in corporate finance research were collected from Wind Info, which provides the equivalent of Compustat data on Chinese publicly listed firms. We then manually collected and merged information on firms' real estate assets from their annual financial reports. Market values of their property holdings were recovered via procedures described more fully below. This provides us a unique data set on listed firms' real estate asset holdings in China.

The second data set is a panel on constant quality land prices across 35 major Chinese cities from 2003-2011 based on other work we have done (Deng, Gyourko and Wu, 2012). This series is constructed from sales of vacant land by local governments to residential property developers. We are able to adjust for site quality in a variety of ways to construct a hedonic price index for land in each market. This is the first such series available for such a wide cross section of Chinese markets. As is discussed below, we believe this series is far superior to the other available sources on property values—namely, house price data reported by the Chinese government. Land is the residual claimant on property value and it, not structure value, is what changes over time. Hence, it is preferable to measure land values directly. In addition, we are able to control for quality changes over time, while the official sources are not.

We combine these data sources to provide the first estimate of the impact of changing real estate collateral values on the investment and spending behavior of Chinese firms. In stark

contrast to the recent findings referenced above on American corporations, we find no evidence of a collateral channel effect in China. The typical concern when running investment equations of the type done by us and others in this literature is that the estimates are biased upward because of endogeneity concerns that are discussed more fully below. Hence, it is highly unlikely that our results are being driven by standard econometric concerns about this type of work. Noisy data can explain statistically insignificant results, but our estimate is a fairly precise ‘zero’, so it does not appear that defects in our new data series are responsible for our key conclusion either.

We argue that the nature of some Chinese firms, as well as financial market norms and regulation, largely account for there being no collateral channel effect. Theory tells us that there should be no collateral channel effect unless firms are financially constrained. State-owned enterprises, which tend to be the largest firms in China, are widely alleged to have special relationships with the government-controlled banks (e.g., see Lin and Tan, 1999; Allen, Qian and Qian, 2005; Poncet, Steingress and Vandebussche, 2010), so these firms should be unconstrained financially. Essentially, they do not need to rely on rising collateral values to get all the funds they need. When we disaggregate by type of firm, the behavior of state-owned enterprises never is affected by the value of their real estate. However, we typically do not find an economically or statistically meaningful collateral effect for non-state owned enterprises either. Here, we suspect that norms and conditions in the Chinese lending markets help explain this outcome. Purely private Chinese firms generally find it very difficult to renegotiate loan terms or get new loans under broader bank quotas even if the underlying collateral value changes. This cuts off the initial impetus for a collateral channel effect.

In sum, we conclude that China is different from the U.S. and Japan, and that there is no material collateral channel effect generated by the changing fortunes of its property market. That

said, we emphasize that this does not mean that a significant real estate downturn would not harm the Chinese economy. It almost certainly would, just not through the collateral channel. The real estate industry constitutes a very large share in China's national GDP growth, up to 12% according to some estimates.¹ Thus, the sector is a large employer in its own right and a major demander of raw and processed materials from other sectors of the economy. Hence, the direct impact could be large, even without a collateral channel effect amplifying the cycle via firm investment behavior.

The plan of the paper is as follows. The next section describes the unique real estate and firm data we bring to bear in our estimation of the collateral channel effect. Section III then discusses our estimation strategy and reports results. There is a brief conclusion.

II. Data

We bring two new data sources to bear on this question, both of which are unique to the study of the Chinese economy. The first is a panel on land prices across 35 Chinese cities, and the second is a panel on firms not directly involved in the real estate industry. The remainder of this section describes both in detail.

II.A. Land Value Data

Our land price series is based on sales of raw land by local governments, and is described more fully in Deng, Gyourko and Wu (2012). While raw land sales are only very rarely observed in most countries, this is not the case in China. The Chinese government owns all the urban land in the country and allows private parties to purchase use rights, for up to 70 years for

¹ According to the estimates by Deng, et. al. (2011), the contribution of real estate-related industries to China's GDP growth hovered between 6-10% over the past decade, and peaked at 12.6% in 2009.

residential purposes (i.e., technically, this is a leasehold estate).² We treat the upfront lump sum payment as the transactions price for land because there are no further rental payments required. A 2002 ruling by the Ministry of Land and Resources required local governments to sell land via some type of public auction process and to publicly report the winning bidder along with the transactions price.³ Because of this new process, these prices can reasonably be treated as free market values. We also typically observe the land parcel's precise address, designated usage, land conditions upon delivery, and certain planning indicators such as the floor-to-area ratio.

Building upon prior research on the city of Beijing in Wu, Gyourko and Deng (2012), we worked with a leading residential real estate data vendor in China (Soufun) to collect data on all residential usage land sales to private parties in 35 major markets from 2003-2010 (and soon to be 2011). Figure 1 maps the cities covered. The geographical breadth of cities in our sample is noteworthy. We are not limited to a few coastal markets that allegedly had the biggest booms. Table 1 reports summary statistics on the sample. We have complete data dating back to 2003 for 15 markets, with the rest entering the sample in subsequent years. The number of transactions per market ranges from 25-50 depending upon the year.

Figure 2 plots the percentage change in land prices for our 35 markets in constant 2009 yuan. These reflect changes in constant quality prices arising from a city-level hedonic equation

² Firms can still use a leasehold estate as collateral when borrowing. That is, the leasehold of the collateral properties can and will be transferred to the lender if the borrower defaults. For example, 15 of the 16 commercial banks listed in Shanghai or Shenzhen regularly release the value and breakdown of repossessed assets they seized from defaulted loans. At the end of 2010, the total book value of their repossessed assets was 14.85 billion yuan RMB, of which properties accounted for 11.89 billion, or 80.10%, with the rest from equipment and plants, securities, etc.

³ Prior to this ruling called the 11th Provision, most transactions of urban land parcels were done by negotiation between a developer and a local government. This process was criticized for being opaque and open to corruption. For our purposes, the prices that resulted seem likely to be below free market levels, with the degree unknown and possibly changing over time depending upon local circumstances. Currently, all transactions must be done via public auctions, including regular English auctions (*pai mai*), two-stage auctions (*gua pai*), and sealed bids (*zhao biao*). See Cai, Henderson and Zhang (2009) for a comparison of these three types of auctions.

of the following form that was estimated via ordinary least squares.⁴ The log of real transactions price is the dependent variable. Quality controls on the right-hand side include: (a) the parcel's distance to the center of the corresponding city, which is measured after mapping the precise location of each site with GIS software; (b) the distance to the nearest subway station; this variable is relevant in 10 of the 35 cities with operating subway systems during our sample period; (c) district dummies which control for local/neighborhood-level fixed effects not captured by the two previous location controls; (d) a set of physical attributes including the size of the parcel (in land area), the density permitted on the site when built, and whether the parcel is leveled on delivery; (e) in some cases a small portion of a residential land parcel is designated for affiliated commercial properties, public establishments, or public housing units; we control for such conditions via a set of dummies; (f) the parcel's transaction form as reflected in whether it was purchased via sealed bidding, regular English auction, or two-stage auction; and (g) year dummies, where coefficients of the year dummies are used to create the constant quality price index.⁵

There clearly is substantial volatility in land price appreciation across and within cities over time. Many cities, not just the big coastal markets of Beijing, Shanghai and Shenzhen, have experienced considerable booms and busts in land values over time. Table 2, which is taken from Deng, Gyourko and Wu (2012), reports summary statistics on average annual land price growth over time. Table 3, also from Deng, Gyourko and Wu (2012), highlights that land values

⁴ We also conducted a two-stage Heckman estimation to control for potential bias arising from the fact that there were a total of 371 parcels listed that failed to result in transactions (either because there were no bidders if there was an auction or the bid prices were lower than the local governments' reserve prices, which is relevant for cases involving sealed bids). If these failures are disproportionately concentrated in certain periods such as the financial crisis, selection bias would result in an overestimation of the price index for that period. That said, we could not find any statistically significant impact for the inverse Mills ratio estimated from our first-stage probit model.

⁵ Our land price hedonic works well in each of the 35 cities. The city-level coefficients are almost always consistent with expectations, and the null that there is no explanatory power for our right-hand side variables always is easily rejected. See Deng, Gyourko and Wu (2012) for more on the hedonic model. All underlying results are available upon request.

are much more volatile than house prices (and other factors of production in housing) as theory predicts for the residual claimant on property value. Standard deviations in land prices typically are in the 20%-40% range, which is about four times that of any other variable reported in Table 3.

It is the cross sectional and time series variation in these constant quality land price series which we use to impute the change in firms' collateral value.⁶ While we documented substantial volatility in land values over time across markets, it also is the case that there has been strong trend growth in values. Deng, Gyourko and Wu (2012) report that compound real annual price appreciation has been over 20% for 17 of our 35 markets, with 10 of the remaining 18 cities having average compound annual growth rates between 10% and 20%. Hence, if Chinese firms are financially constrained and collateral value is important in obtaining the desired amount of debt, there has been a huge increase in those values over time on average, with substantial variation across markets.

We believe these data are far superior to any alternative, the most prominent of which are two government-provided series. One is called the Average Selling Price of Newly-Built Residential Index. This reports the simple average of transactions prices as measured by total sales values divided by the total amount of housing square footage permitted on the land. The other series, officially termed "Price Indices in 70 Large and Medium-Sized Cities", is a measure of the change in average prices on unit sales within individual housing complexes over time. More specifically, this index is calculated by first computing the average sales price of new units

⁶ We use residential land prices because it is not yet feasible to create an analogous index for commercial properties. Theory suggests these two series should be highly correlated, since land is substitutable between these two uses on the margin. As a robustness check, we calculated the correlation coefficient between the average transaction prices of newly-built residential buildings and commercial properties as reported by the National Bureau of Statistics of China in our 35 city sample. It was a strongly positive 0.64. Chaney, et. al. (2011) report similar findings in their robustness checks.

each month in each distinct housing complex. The series reported by the government then is the transactions-volume weighted average of each complex's average price changes over time.

The first series is plagued by a complete absence of hedonic adjustment, as there is no attempt to adjust for quality differences across markets or drift over time. As our results and those of Wu, Deng and Liu (2011) show, not effectively controlling for quality leads to substantial biases.⁷ As long as structure is in anything approaching elastic supply, what one wants to measure is land value anyway. Deng, Gyourko and Wu (2011) and Wu, Deng and Liu (2011) also show that the second series results in downwardly biased estimates of price growth, with much lower volatility than exists in reality. Both sets of authors recommend a hedonic approach to control for quality changes over time, which is the procedure used here.⁸

II.A. Firm Data

We collected data on publicly-traded firms listed on the Shanghai or Shenzhen stock exchanges. There are 1,291 firms listed on or before 2003 on these two exchanges. We get to our final sample size of 453 firms as follows. First, we exclude firms delisted during or before 2010. We also drop those with measured negative equity and those involved in a major takeover operation during the sample period, as we suspect either data error or some other aspect of firm strategy is likely to complicate any potential relationship between real estate collateral value and investment and other spending behavior. Next, firms operating in the industries of “finance”, “real estate”, and “construction” are dropped because it seems highly likely that the relationship between firm investment behavior and real estate price fluctuations may be determined by a

⁷ Average annual appreciation in our hedonic index is about five percentage points higher than in the unadjusted price series, which suggests that parcel quality has been falling over time on average. The declining quality of location with more sites being located in outlying areas as China has rapidly urbanized is an important factor, but this does vary by time and market to some extent. See Deng, Gyourko and Wu (2012) for more on this.

⁸ More sophisticated repeat sales procedures such as those pioneered by Baily, Muth and Nourse (1963) and Case and Shiller (1987, 1989) are not feasible in China. The vast majority of its housing is new, so there are very few cases in which a unit has sold more than once. Hence, the older, but still reliable hedonic approach must be used for quality control purposes.

mechanism other than the collateral channel effect in these business sectors. Firms in the industries of “agriculture”, “mining”, “production and supply of electricity, gas and water” and “transportation and storage” also are excluded because they tend to own properties outside of urban areas, and we cannot impute land price changes outside of the 35 major markets listed above. Thus, our final sample is restricted to firms in the industries of “manufacturing”, “information technology”, “wholesale and retail”, “social service”, and “media and culture”.⁹ Finally, we narrow our focus to firms with headquarters in 35 major cities for which we have a reliable land price series that is used to impute the value of real estate collateral over time. This leaves us with a balanced panel of 453 firms with 3,624 firm-year observations during 2003-2010.¹⁰

Determining the market value of these firms’ real estate asset holdings is a critical task for our estimation. The nature of Chinese accounting and reporting practices is such that three major categories of assets on the balance sheet are involved in constructing our measure. One is “Buildings” (a sub-entry of “Fixed Assets”, the equivalent of “Property, Plant and Equipment” in China’s accounting codes); a second is “Land Ownership” (a sub-entry of “Intangible Assets”); and the third is “Investment Properties”. Table 4 provides more detail on related accounting codes, including a minor adjustment in 2007. Unfortunately, none of the available listed firm electronic databases in China presently provides full information on all three categories of property assets. Consequently, we manually collect this information from the original version of the firms’ annual financial reports.

While we believe this is the first systematic collection of non-real estate firms’ property holdings, this is only the starting point for our analysis. As with the Compustat data on U.S.

⁹ According to the official industry codes issued by the China Security Regulatory Commission, there are also a few firms defined as in “Multiple Industries”. These companies are grouped based on their largest sales sector.

¹⁰ We are in the process of updating with 2011 data.

corporations, financial reports include values based on historic cost, not current market values. We follow the procedures adopted by Chaney, et. al. (2011) to translate these book values into market values. From the financial reports, we know both the original book value and the current book value after depreciation. Then, following certain rules on depreciation, the average age of properties can be computed.¹¹ Finally, the book value is updated to the market value using the city-level residential land price index described above after 2003, a newly-built house price index between 2000 and 2002¹², and the city-level CPI index before 2000. Because we do not know the exact address of each property in a firm's portfolio, we follow Chaney, et. al. (2011) and Cvijanovic (2011) in presuming that a firm's properties are concentrated in the city of its headquarters.¹³

We next develop an estimate of annual change in value of firm real estate asset holdings. Our preferred measure is one that reflects changes in the market value over time of real estate assets owned by the firm in the reference year of 2002 at the very beginning of our sample period. Chaney, et. al. (2011) and Cvijanovic (2011) both do something similar to guard against bias arising from the potentially endogenous decisions of firms to expand or reduce their real estate holdings in response to (or in conjunction with) market price changes. Thus, our collateral value measure is defined as:

¹¹ We use the following strategy to guide us in these calculations. If a firm explicitly describes its depreciation method in the appendix of its financial reports, we adopt that specific rule for that firm. Otherwise, we follow conventional rules on depreciation for China, which reflect an average of the different rules published by the listed firms in our sample: for the items of "Building" and "Investment Properties", it is assumed that the properties are straight-line depreciated with 25 years of depreciable life and 5% remains; for "Land Ownership", the corresponding assumption is straight-line depreciation method, 40 years of depreciable life, and 0 remains. Western readers may be surprised by the depreciation of land, but it does make sense because this technically is a leasehold estate position.

¹² This house price index is provided by Institute of Real Estate Studies at Tsinghua University.

¹³ Both Chaney, et. al. (2011) and Cvijanovic (2011) investigate the robustness of this assumption using added information from firm 10-K filings. Unfortunately, similar documents and data are not available in China. We addressed the robustness of this assumption as follows. First, we pared down the sample to firms headquartered in the 32 cities outside of the three national financial centers of Beijing, Shanghai and Shenzhen on the presumption that firms located in the other 32 cities are less likely to be geographically dispersed in their business and, hence, real estate asset holdings. All our key results reported below still hold in this "geographically concentrated" group. They are available upon request.

$$RATIO_REV1_{i,t} = [REV_{i,2002} \times \prod_{j=2003}^{t-1} (1 + LPG_{c,j}) \times LPG_{c,t}] / ASSET_{i,t-1}$$

where, $REV_{i,2002}$ is the market value of real estate assets owned by firm i at the end of 2002 computed based on the procedures described above, $LPG_{c,j}$ is the annual growth rate in the local land price index for firm i 's headquarters city c in year j , and $ASSET_{i,t-1}$ is the total assets of firm i at the beginning of year t (i.e., at the end of the previous year).

For robustness, we also calculated a second proxy, which measures the market value change of real estate assets held by the firm exactly at the beginning of that year:

$$RATIO_REV2_{i,t} = [REV_{i,t-1} \times LPG_{c,t}] / ASSET_{i,t-1}$$

where $REV_{i,t-1}$ is the market value of real estate assets owned by firm i at the beginning of year t (i.e., at the end of the previous year). We experiment with both measures because it is not obvious *a priori* what the optimal balance is between potential endogeneity bias and measurement error.

In addition to our measures of changes in underlying real estate collateral, we also use a number of variables describing other firm characteristics. As noted above, these are from Wind Info, which is a supplier of 'Compustat-type' data on Chinese companies.¹⁴ These include the ratio of net investment on fixed assets (property, plant and equipment) to firm asset value ($RATIO_INV$), where the numerator is defined as expenditures on fixed assets less cash inflows from disposing of existing fixed assets over the year and the denominator reflects total assets at the beginning of the relevant year ($ASSET$), $RATIO_LOAN$ which is defined as the net change in loan balances scaled by firm assets, $RATIO_EBITDA$, which reflects earnings before interest tax, depreciation and amortization (again scaled by firm assets), $RATIO_CASH$ which reflects the net

¹⁴ See their website at www.wind.com.cn for more detail.

change in cash holdings divided by assets, *RATIO_SALARY* which is defined as total salary payments divided by firm size, *RATIO_DIVIDEND*, which is total dividend payments scaled by firm assets, *RATIO_FAINV* which is the ratio of net investment on financial assets such as stocks and bonds to firm asset value, and *EMP*, which is the number of employee per million yuan of firm assets. Other variables include the market-to-book ratio (*MBR*) and leverage level at the beginning of the year (*LEVERAGE*, defined as total debt on the balance sheet divided by asset value), and the change in share of long-term loan (i.e., loans with the period of more than 1 year) in total loan balance during the year (*LONGLOAN*).

We also collected information on the total amount of government subsidies received by a firm during each year. This includes both explicit monetary subsidies and implicit subsidies from discounted tax rates. As with the other variables, this also is normalized by the total assets of the firm (*RATIO_SUBSIDY*). It serves as a proxy of government support in some of the robustness checks discussed below.

Table 5 reports the summary statistics of the variables, with each having been winsorized at the 5th percentile to eliminate extreme outliers in the data series. One noteworthy feature is the large magnitude of the annual market value change of the listed firms' real estate assets. On average, it is equivalent to about 6% of a firm's total assets if we only take properties owned in the reference year into account, and to over 7% if all real estate assets are included.¹⁵

Table 6 then reports the number of firms in our sample broken down by whether or not they are state-owned enterprises (SOEs). This firm characteristic also comes from the Wind Info data source.¹⁶ SOEs account for about three quarters of these 453 firms, although that proportion

¹⁵ The fact that the average value of *RATIO_REV2* is larger than *RATIO_REV1* implies that the listed firms generally are expanding their real estate holdings over our sample period.

¹⁶ More detailed information is available, as we can tell whether a SOE is directly controlled by the central government or by some type of sub-national government. See Deng, et. al. (2011) for more details on the distinction

declines over time due to ongoing reforms of SOEs within China. Table 7 then compares the values of these variables across the two types of firms. SOEs and non-SOEs differ in several aspects. SOEs tend to be much larger than non-SOEs. They also pay out more in salaries to their employees, but they are less profitable, pay fewer dividends, and have lower market-to-book ratios. However, both these groups experience almost the same degree of change in the market values of their real estate assets during the sample period. And, the difference in their fixed assets investment or borrowing characteristics also is statistically insignificant.

III. Empirical Implementation and Results

Chaney, et. al. (2012) provide an excellent derivation and description of a standard model of investment when a firm suffers from a binding financing constraint.¹⁷ That model leads those authors (and others, including us, working in this literature) to reduced form investment equations of the following type:

$$(1) \text{RATIO_INV}_{i,c,t} = \alpha + \beta * \text{RATIO_REV}_{i,t} + \gamma * \text{LP}_{c,t} + \delta_t + \eta_i + \varphi * \text{OtherControls}_{i,t} + \epsilon_{i,t},$$

where i indexes the firms, c denotes the city of their headquarters, and t reflects the year of the observation. RATIO_INV and RATIO_REV are as defined just above, LP is the land price index in the city where the firm is located, δ and η capture year and firm fixed effects, respectively, and OtherControls includes standard firm measures of leverage (total debt/asset value), market-to-book value and cash flow (EBITDA more specifically) used in these types of regressions. The investment and collateral value measures naturally are scaled to control for firm size

between these two groups. Because all our key conclusions are robust to this breakdown, we only report results for all SOEs versus non-SOEs.

¹⁷ See their on-line appendix for this material. It may be downloaded at www.princeton.edu/dsraer/theoryRE.pdf.

differences.¹⁸ Time and firm fixed effects are included so that identification effectively comes from variation over time within firm. One of the two real estate variables is the log of the land price index (*LP*) in the city where the firm is headquartered. This variable is intended to control for broader real estate market changes that could influence investment behavior independent of the value of an individual firm's collateral.

The coefficient of interest in this regression is β which captures how changes in the value of a firm's real estate collateral (*RATIO_REV*) affect investment (*RATIO_INV*). The underlying theory indicates that there is no reason to believe that β must be positive. For example, if firms were unconstrained financially in the sense that they were cash rich, or could always borrow as much as they needed to fund their desired investment programs, then changes in the value of their owned assets would not influence investment behavior. Naturally, the prediction is different for financially constrained firms that borrow some fraction of the collateral value of the assets they can pledge to lenders. For these firms, $\beta > 0$. Overall, the estimate of β using a panel of firms reflects the combination of how many of them are financially constrained, how binding those constraints are, and how easy it is to pledge the underlying collateral to increase debt capacity (Chaney, et. al., 2011).

While it is fairly straightforward to generate a specification such as equation (1) from a simple model of investment with financial constraints, the challenge is obtaining unbiased estimates of β . The typical worry is that OLS yields upwardly biased results on the collateral channel effect. Perhaps the most obvious reason is due to reverse causality. If a firm is large

¹⁸ Note that we use asset value in the denominator rather than the more typical measure in the literature of overall property, plant and equipment (which are called "fixed assets" in China) on the firm's balance sheet because of the nature of the available Chinese balance sheet data. As depicted earlier in Table 4, part of a firm's real estate holdings are not included in the item of "Fixed Asset" on its balance sheet. In particular, the 2007 adjustment of accounting codes separated the leased-out properties from "Fixed Asset", and put it as part of a new, independent item called "Investment Properties" on the balance sheet. This makes the fixed assets series inconsistent over our sample period, which is why we scale by assets. The 2007 adjustment did not apply to the cash flow figures, so it does not affect our measure of *RATIO_INV*.

enough in its market, its own investment program might affect factor prices, including local land values. Similar effects could occur in markets in which multiple firms from the same industry co-locate. In this latter case, common shifts in investment patterns unrelated to collateral value well could be captured in the estimate of β from equation (1) if the firms' investment behavior bids up local land values. Upwardly biased estimates of β also would result if large land-holding firms are especially sensitive to local demand shocks (for whatever reason) and our real estate variables proxy for local demand to any significant extent.

The recent literature on collateral channel effects on U.S. corporate investment exploits differences in local market supply elasticity to deal with this bias (Chaney, et. al., 2011; Cvijanovic, 2011). The basic strategy is to instrument for real estate values using the interaction of a demand shifter (e.g., mortgage rates) with the local supply elasticity, along with firm and time fixed effects. The underlying logic is as follows. Demand shifters should show up in higher prices the more inelastic is local supply. If supply were perfectly elastic, prices should not change at all. The measure of supply elasticity (typically from Saiz (2010)) is based on fixed geographic factors such as the amount of water and the slopes of land plots in the market area, so it provides plausibly exogenous variation in real estate values due to changes in demand. As noted in the Introduction, that type of instrumental variables estimator yields economically large collateral channel effects on investment among U.S. corporations.

Unfortunately, there are no similarly high quality measures of local supply elasticity for our Chinese markets, so we cannot implement a similar strategy here. Hence, we begin by estimating a version of (1) that does not instrument for real estate value, keeping in mind that the reported estimate of β is likely to be biased upward.¹⁹ That said, if we do not find a statistically

¹⁹ We do other things to try to control for this bias. For example, our specifications also include interactions of the initial firm traits with the local land price index. As Chaney, et. al. (2012) note, this helps control for potential

and economically large collateral channel effect, we can be sure that it does not exist, as the biases from such a specification work in the direction of finding one.

Table 8 reports our baseline findings. The precise specification estimated is very similar to equation (1), except that it includes interaction terms of the initial firm controls with local land prices. The first column reports estimates using the full sample of firms, regardless of type. The estimate of β on our measure of the real estate collateral variable, *RATIO_REVI*, is a very small and statistically insignificant -0.0013. Thus, there is no evidence of a collateral channel effect in the Chinese data, as firm investment behavior is uncorrelated with changes in the value of the real estate they own.

This average could be masking important heterogeneity across types of firms, as state-owned enterprises, which constitute the bulk of our firm sample well could be unconstrained. If so, they would not be expected to exhibit any collateral channel effect on their investment behavior. Hence, columns 2 and 3 of Table 8 report estimates of the same specification on subsamples of SOEs and non-SOEs. The results are not meaningfully different. It is the case that the estimate of β for SOEs is almost precisely 0, but we cannot reject a null of zero for non-SOEs, and we cannot reliably discriminate between the coefficients across the two types of firms.

The absence of a collateral channel effect also is not due to possible measurement error arising from our holding constant the quantity of the firms' real estate holdings at their end of 2002 levels. While we prefer that measure (*RATIO_REVI*) because it better addresses possible upward bias in β , we obtain very similar results if we use *RATIO_REV2* instead of *RATIO_REVI*

upward bias in β that might result from potential endogeneity arising from the decision to own real estate in the first place. If firms that are more likely to own real estate also are especially sensitive to local demand shocks, equation (1) will overestimate the collateral channel effect. Our inclusion of the firm traits and their interaction with local land prices helps control for any fixed firm-level correlation between investment and real estate values. We have no good instrument to deal with variation that may not be fixed, but this is not costly for us, as we do not find a meaningful collateral channel effect in any event. Hence, we have no need to account for any upward bias.

as our measure of real estate collateral. For example, the coefficient on this measure in the non-SOE sample is -0.0055 (standard error=0.0140) versus -0.0107 (standard error=0.0174). This is slightly more positive than what is reported in Table 8, but the difference is statistically and economically meaningless.²⁰ And, the standard errors are small enough that even the implied economic impact from a coefficient two standard deviations above that reported in Table 8 still is small. For example, if we consider the results for non-SOEs, the group of firms for which a sizeable collateral channel effect is most plausible, a coefficient of 0.0241, which is two standard deviations above the -0.0107 value reported in column 3 of Table 8, implies only five percent of a standard deviation increase in investment per dollar of assets among those firms. Given that virtually any endogeneity-driven bias arising from our simple OLS specification is to raise β above its true value, this implies a fairly tight estimate around zero of β and strongly suggests that there is no collateral channel effect operating among non-real estate firms in China.

The absence of any meaningful economic or statistical relationship between real estate collateral value and firm investment raises the question of whether firms are even borrowing more at all when real estate values are higher. Table 9 reports those results using the annual change in total debt per dollar of asset value as the dependent variable for the full sample of firms and then the breakdowns for SOEs and non-SOEs. Here, we find that real estate collateral values are positively correlated with firm borrowing, but the impacts are small in both economic and statistical terms. On average, Chinese firms are neither borrowing nor investing more when owned property increases in value.

The results for SOEs are readily explainable in terms of their not being financially constrained. Indeed, one could interpret our findings for them as evidence in support of the

²⁰ This pattern holds for all other specifications reported below. To simplify the presentation of the results, we only report findings using *RATIO_REVI* as the collateral value measure in all tables below. All results are available upon request.

claims by many that they are specially favored within the Chinese economy (Lin and Tan, 1999; Allen, Qian and Qian, 2005; Poncet, Steingress and Vandebussche, 2010), and have no need to rely on increasing collateral value to secure financing. However, that cannot be the story for non-SOEs, who are much more likely to be financially constrained. Features of the Chinese banking system and capital markets can help account for the absence of a collateral channel effect for these firms. The aggregate volume of credit is tightly controlled in China, with the government often imposing quotas on lenders in different cities. Even if underlying collateral value owned by the firm increases, a binding quota implies that no further lending or borrowing can or will take place, as illustrated by Figure 3. Presume that the existing loan quota amount is given by L_1 in this figure. Even if a boom in the property markets leads to collateral values increasing from A to B, there can be no net increase in loans beyond L_1 . Unless the loan quota is increased to L_2 as in this figure, there cannot be a collateral channel effect from rising property values.²¹

Regulatory norms also could help explain why we do not observe a collateral channel effect among non-SOEs, even if loan quotas are not binding. Common practice in the Chinese lending markets does not allow firms that experience positive appreciation on existing assets pledged as collateral against current loans to use that enhanced value to obtain new loans or better terms on the existing loans. This fixity in loan terms cuts off any possibility for a

²¹ Strictly speaking, this suggests that the collateral channel effect may be asymmetric for non-SOEs. With the loan quota of L_1 , any collateral value increase beyond A cannot help expand firms' borrowing, but collateral value declines below A may erode firms' borrowing and investment capacity. During our 2003-2010 sample period, there are few city-years experiencing land price drops, which makes it difficult for us to test for the existence of such asymmetry. But several major cities including Beijing and Shanghai have experienced significant land price declines in 2011, so subsequent data updates may allow for such a test in future versions of the paper.

collateral channel effect.²² Added properties could be used as collateral for additional debt, of course, but that is very different from being able to exploit increased value on existing assets.

The prospect of a binding loan quota constraint suggests that the best case for observing a collateral channel effect among non-SOEs would be in the recent 2009-2010 stimulus period, when those quotas were raised. In Figure 3, this would be the equivalent of raising the loan quota from L_1 to L_2 . Tables 10 and 11 report regression results analogous to those in Tables 8 and 9, except that they include the interaction of our firm-level real estate collateral variable with a dummy for the stimulus period. Even in the stimulus period, Table 10's results show no evidence that non-SOEs were engaged in investment booms that are correlated with higher owned real estate values, and we know from Figure 2 that values were increasing markedly in most markets during this period. The same conclusion holds for SOEs, but that is to be expected given their likely unconstrained status.²³

Interestingly, the results in column 3 of Table 11 do show a statistically significantly higher amount of borrowing by non-SOEs (but not SOEs, as expected) during the stimulus period associated with their appreciated real estate assets. The impact of higher collateral value during the stimulus period (which equals 0.0344 as the sum of $-0.0499+0.0843$) suggests that a \$1 increase in real estate collateral value will raise non-SOEs' loan balance by about 3 cents, controlling for other factors. How large this is in economic terms is perhaps better seen with the following calculation. The standard deviations of *RATIO_REVI* and *RATIO_LOAN* for non-

²² In most cases, non-SOEs also cannot obtain better loan terms simply by prepaying their existing loans. There is no guarantee that private firms can get new (or more) loans after prepaying unless loan quota amounts have been relaxed. This is one reason the prepayment of corporate loans is rare in China, although there are no accurate statistics we could find on this issue (which is another indication of how rare this practice is).

²³ Another possibility is that non-SOEs operate in industries that the central or local governments want to discourage. In that case, it could be that they cannot expand for other regulatory reasons independent of the collateral channel effect. To investigate this, we collected data on the level of subsidy received by the firm, as described for the *RATIO_SUBSIDY* variable in the previous section. We found no evidence that non-SOE investment behavior varied by the degree of subsidy.

SOEs during the stimulus period are 0.1881 and 0.0844, respectively, which implies that a one standard deviation increase in collateral values is associated with about 8% of a standard deviation increase in loan balance (i.e., $0.1881 \times 0.0344 / 0.0844 \approx 0.0767$). While this is not zero, it also indicates that non-SOEs were not increasing overall leverage by huge amounts during the stimulus period because of rising underlying real estate collateral values.

If non-SOEs were borrowing a bit more, but not investing more in property, plant and equipment, what were they doing with the funds? Table 12 provides some answers. Six potential spending outcomes other than fixed asset investment are investigated. These include hiring more employees (*EMP*), increasing salary payments (*RATIO_SALARY*), expanding equity payouts (*RATIO_DIVIDEND*), investing in financial assets such as stocks or bonds (*RATIO_FAINV*), replacing short-term debt with long-term debt (*LONGLOAN*), or doing nothing but simply holding more cash (*RATIO_CASH*). The results in Table 12 show statistically significant correlations of increasing real estate collateral value during the stimulus period only with firm employment levels and cash holdings. While statistically significant, the impact on employment is small in economic terms. A one standard deviation of increase in collateral value only results in about five percent of a standard deviation increase in employment ($0.1881 \times 0.2048 / 0.7836 \approx 0.0491$) for non-SOEs during the stimulus period. The economic significance of the effect on cash holdings is larger. Those coefficients imply that a one standard deviation increase in collateral value is associated with about one-fifth of a standard deviation increase in firms' cash holdings ($0.1881 \times 0.0934 / 0.0822 \approx 0.2137$). In sum, it appears as if non-SOEs used the added debt they were able to obtain during the stimulus period when loan quotas were relaxed to hold more cash.

We cannot tell why non-SOEs did not ‘splurge’ more with their added debt, but it could be they understood the change was not sustainable. With the stimulus package, the Chinese government only temporarily relaxed the loan quota, but did not unfold any fundamental reform in the financial system which could be expected to systematically ease non-SOEs’ access to bank loans over the long term. If the entrepreneurs running the non-SOEs expected the loan quota to decrease back to old levels after the stimulus (i.e., from L_2 to L_1 in terms of our Figure 3), it would be unwise of them to spend the added funds on ‘irreversible’ uses such as fixed assets or equity payouts.²⁴ Instead, they appear to have chosen to expand their business by hiring a few more employees, and kept most of the added funds as cash reserves to secure their solvency.

IV. *Conclusions*

Research in macroeconomics and corporate finance reports substantial collateral channel effects on firm investment that amplified the business cycles of the United States and Japan. We provide the first analysis of whether something similar can be expected for China, which also has experienced an extraordinary property market boom that appears to have crested recently. Working with unique data on land values in 35 major Chinese markets and a panel of firms outside the real estate industry, we estimate standard investment equations that yield no evidence of a collateral channel effect.

This is perhaps not surprising for state-owned enterprises which probably are not financially constrained in the sense required by the underlying theory for a collateral channel

²⁴ This may be investing too much foresight and discipline in the non-SOE managements, but it is the case that the debt markets soon reverted back to their formerly difficult conditions for most purely private enterprises. Conditions became so constrained that the Chinese government has begun to seriously consider undertaking a major reform in China’s financial system in early 2012 to provide more secure financing to these firms. See reports from the *Wall Street Journal* (“China Tests Financial Relaxation in Wenzhou”, March 28, 2012; “Chinese Premier Blasts Banks”, April 3, 2012) for examples of this.

effect to operate. However, we also find no such effect for non-SOEs, so our average results are not masking important heterogeneity across different types of firms. We believe that norms and regulation in the Chinese capital markets and banking sectors help explain why the collateral channel effect does not operate among these firms in China.²⁵

While our conclusion that a real estate bust in China is unlikely to cause investment by Chinese firms to decline because of decreased underlying collateral values, this does not imply that a bust won't materially harm the economy. It could, and we strongly suspect it will. The direct impact of a major decline in property values on hiring in the construction industry and on demand for raw and processed materials is likely to be quite large, even without amplification from the collateral channel. However, that is a topic for a future paper.

²⁵ Another potential explanation has to do with default risks of non-SOEs. Merton's (1974) classic paper showed that a firm's default probability is importantly influenced by the extent to which its corporate assets exceed its liabilities. This implies that the degree of a firm's financial constraint and its default risks may be highly correlated: typically firms with lower default risk are also less financially constrained, while those facing financial constraints are more likely to default and thus not be favored by lenders. We plan to explore this in detail in future versions of the paper by introducing a proxy measuring individual firm's estimated default probability.
